1 MARIDA Summary

The [MARIDA](#) (Marine Debris Detection and Analysis) article provides an exploration of the application of satellite imagery and computer vision algorithms in the context of marine debris detection. The study specifically focuses on utilizing multispectral satellite images obtained from the Sentinel-2 satellite to develop models capable of accurately identifying and classifying marine debris.

1.1 Dataset

The MARIDA Dataset used in the study consists of 1381 patches, containing a total of 837,357 annotated pixels. Each annotation belongs to one of the 15 classes: Marine Debris, Dense Sargassum, Sparse Sargassum, Natural Organic, Material Ship, Clouds, Marine Water, Sediment-Laden Water, Foam, Turbid Water, Shallow Water, Waves, Cloud Shadows, Wakes, Mixed Water. The pixel-level class distribution can be seen in Figure 1. The patches were derived from 63 Sentinel-2 scenes acquired between 2015 and 2021 with data collected from eleven countries. Each pixel in the dataset is assigned a confidence level of annotation, categorized as high, moderate, or low.

During data preprocessing, Rayleigh reflectance values were extracted at a 10 m resolution for 11 Sentinel-2 bands using the ACOLITE atmospheric processor, excluding the Vapour band (Band 9) and Cirrus band (Band 10).

1.2 Machine learning

For the machine learning techniques, the initial 15 classes were grouped into 11 classes by merging certain water classes into a single super-class. This decision was based on the semantic similarity and similar spectral profiles observed among these classes.

To evaluate the performance of various models for marine debris detection, the MARIDA article considers four different approaches. The first three of them are different Random Forest models: Random Forest with spectral signatures RF_{SS} , with spectral indices RF_{SS+SI} and gray-level co-occurrence matrix $RF_{SS+SI+GLCM}$. The extracted spectral indices were NDVI, NDWI, FAI, FDI, Shadow Index (SI), Normalized Difference Moisture Index (NDMI), Bare Soil Index (BSI) and NRD. To compute the GLCM features, Rayleigh corrected RGB composites were converted to grayscale images, which consequently were quantized in 16 bins-level. The selected GLCM features were Contrast, Dissimilarity, Homogeneity, Energy, Correlation and Angular Second Moment. For those features extraction, a window of size 13 x 13 was used.

The fourth approach is the U-Net architecture. The first input layer of U-Net was modified to adapt to the 11 Rayleigh reflectance Sentinel-2 bands, and the final classification layer was changed to output the 11 MARIDA classes. 4 down-sampling and up-sampling blocks were used, as well as 16 hidden channels produced by the initial down-sampling block. The annotators' confidence level information wasn't used for the training.

1.3 Results

The results of the predicted classes can be seen in the Figure 2. Among the mentioned models, the $RF_{SS+SI+GLCM}$ model consistently achieves the highest scores across all evaluation metrics, followed by RF_{SS+SI} and RF_{SS} and U-Net.

Figure 2: Evaluation scores obtained by RF_{SS} , RF_{SS+SI} , $RF_{SS+SI+GLCM}$ and U-Net for each class.

Regarding the classification of marine debris, RF_{SS+SI} demonstrates the highest scores, while adding the GLCM features does not improve the classification performance results.

2 Research questions

1. How does the performance of the U-net model change when applied to satellite images acquired by different satellites, such as Landsat or MODIS, and how can the model be adapted for cross-platform compatibility?
2. Can the $RF_{SS+SI+GLCM}$ and U-Net models be further improved by incorporating pre-processing techniques, such as cloud masking and denoising algorithms?
3. What are the limitations and challenges of using the ACOLITE Dark Spectrum Fitting algorithm for marine debris detection in satellite imagery, and how do these limitations impact the accuracy and reliability of the results?
4. What are the potential methods for incorporating annotators’ confidence level information into the learning process of U-Net, to improve the classification of challenging cases?
5. How does the performance of the $RF_{SS+SI+GLCM}$ model compare to other deep learning architectures, such as Mask R-CNN or EfficientDet, for marine debris detection in satellite imagery?
